This paper sets out alternative best practice approaches to marginal cost pricing of rail infrastructure adopted in a number of EU Member States. It draws on the findings of a report submitted to the European Commission in June 2002 and provides a summary of two different approaches to the adoption of marginal cost pricing. The Swedish/Finnish approach uses econometric modelling to estimate marginal wear and tear costs whereas the UK model first provides a top-down estimate of the aggregate level of variable costs across the network and then uses relationships between vehicle characteristics and wear and tear costs to allocate the aggregate level of variable costs across vehicle types. Significant differences between countries are found in the variability of infrastructure wear and tear costs to levels of traffic. The resulting derived marginal cost also differ widely. The paper provides possible reasons for these differences but recognises that the understanding of the interface between wheel and rail and hence knowledge of cost causation remains fairly limited. The findings of the paper therefore need to be read in the context of further research being required into railway infrastructure cost causation.

---

1 An earlier version of this paper was presented at the second seminar of the IMPRINT-EUROPE Thematic Network: “Implementing Reform on Transport Pricing: Identifying Mode-Specific Issues”, Brussels, 14th/15th May 2002.
1. Introduction

An expert group on rail infrastructure charging (‘the expert group’) was set up by the European Commission in September 2001 with a remit to report on best practice in rail infrastructure charging, consistent with the charging requirements of Directive 2001/14/EC. The expert group consisted of members with practical experience in the application of differing charging frameworks throughout the EU and who represented rail network operators, government departments and regulators. The Member States who took part in the infrastructure charging expert group were: Germany, France, Italy, Austria, Portugal, Finland, Sweden and the UK.\(^2\) Existing charging policy only in these countries was considered. The expert group reported its findings to the European Commission in June 2002. Since this time, a number of Member States have been developing charging systems compatible with the requirements of Directive 2001/14/EC. In addition, there has been a change of infrastructure manager in Britain (Network Rail has acquired Railtrack) and a major access charges review, following the periodic review of access charges in October 2000, has been completed in December 2003. This paper does not include an assessment of these developments.

The main charging provisions of EU Directive 2001/14/EC are as follows:

- charges shall be set at the cost that is directly incurred as a result of operating the train service (that is, the marginal cost resulting from operating the service);
- a charge may be included which reflects the scarcity of capacity during periods of congestion;
- the infrastructure charge may be modified to take account of the cost of the environmental effects caused by the operation of the train. Charging of environmental costs which result in an increase in the overall revenue accruing to the infrastructure manager shall however be allowed only if such charging is applied at a comparable level to competing modes of transport; and
- charges may be averaged over a reasonable spread of train services and times.

Specific exceptions to the above principles are allowed as follows:

- in order to obtain full recovery of the costs incurred by the infrastructure manager a Member State may, if the market can bear this, levy mark-ups on the basis of efficient, transparent and non-discriminatory principles; and
- for specific investment projects, the infrastructure manager may set higher charges on the basis of the long-term costs of such projects if they increase efficiency and/or cost-effectiveness and could not otherwise be undertaken.

There are also provisions in the Directive related to discounts (generally allowed only where such discounts reflect actual cost savings to the infrastructure manager), reservation charges (to discourage capacity being requested and not used), and compensation schemes for unpaid environmental, accident and infrastructure costs of other modes.

This paper summarises the main findings of the expert group, reporting on examples of identified best practice in relation to the determination of marginal costs. No single country yet implements ‘pure’ marginal social cost pricing although there are examples of good

\(^2\) The Netherlands also joined the working group for the final meeting.
practice in implementing individual components of marginal cost. These individual components consist of:

- the marginal cost of maintaining and renewing the infrastructure (wear and tear costs);
- marginal environmental and accident costs;
- marginal congestion costs; and
- scarcity costs.

The paper highlights areas of inconsistencies between countries (Finland, Sweden and Great Britain) in estimating wear and tear costs, even where marginal cost pricing is applied. The paper does not deal with the potential difficulties in implementing marginal cost pricing since these have been considered in papers presented at previous IMPRINT seminars.\(^3\)

Whilst the expert group reviewed current state-of-the-art approaches to marginal cost pricing, it is recognised that knowledge of cost causation and the interface between wheel and rail is far from well understood. Further research into cost drivers needs to build on the approaches reported in this paper to estimating marginal costs. Efficient costs and prices, providing appropriate price signals, can only be established if detailed and accurate cost information is available. Therefore the assessment in this paper, particularly in relation to the suggested reasons for the wide cost differences between countries, should be treated in the context of the preliminary nature of the knowledge in this field.

The remainder of this paper is structured as follows. Section 2 discusses two alternative ‘best practice’ approaches to deriving marginal costs associated with maintenance and renewal of the infrastructure, including details of the modelling methods used. Section 3 provides a comparative analysis of the results of the approaches applied in different countries. Section 4 discusses best practice in relation to other components of marginal cost and Section 5 provides some brief conclusions.

2. Marginal cost pricing – wear and tear costs

A diversity of approaches exist in establishing and setting usage charges. Two alternative approaches, used by a number of Member States and considered to be best practice in terms of consistency with the provisions of Directive 2001/14, were discussed in detail by the expert group:

- an econometric modelling approach which estimates a total cost function and then takes the first derivative of total cost with respect to gross tonne miles to derive the marginal cost (seen in Finland, Sweden and Austria); and
- an approach which allocates total variable costs across all the different vehicles running on the network, using detailed cost causation engineering relationships (used in Britain).

2.1 The econometric modelling approach

The econometric modelling approach is used in Finland, Sweden and Austria. This assesses marginal costs by examining engineering data and calculating detailed costs built up on an

\(^3\) In particular, see Nash and Matthews (2002)
activity-by-activity basis. It examines the individual relationship between activities and costs and according to cost category and asset type.

Although the modelling conducted in Finland, Sweden and Austria is similar (there are some differences due to data availability, e.g. the Finnish dataset did not include bridges and tunnels), the results of the approach differ between countries, as shown below.

The section below outlines the different ways in which the econometric modelling approach has been pursued in Finland, Sweden and Austria.

**Forming a cost function**

The first step is to define the cost elements which are relevant for short-run marginal costs. By specifying a cost function it is possible to estimate how costs vary with explanatory variables (utilisation level, track length, track quality, etc.). All of these studies have used the type of cost function presented in P. Johansson and J. Nilsson’s study. The cost function for track unit \( i \) at time \( t \) is:

\[
C_{it} = g(Y_{it}, U_{it}, z_{it}, \varepsilon_{it}) = g(x_{it}, \varepsilon_{it})
\]

\( C_{it} \) is the independent variable (maintenance/renewal costs), \( Y_{it} \) is the track length, \( U_{it} \) is the utilisation level (measured in gross tons), \( z_{it} \) is a vector of technical features (including for example the number of switches and crossings, average age of track, main line/secondary line, etc.), \( \varepsilon_{it} \) is a random error term and \( g \) is unknown functional form.

In studies which have used Swedish and Austrian cost data, the independent variable \( C_{it} \) includes only maintenance costs. In the Finnish study two kinds of cost function have been analysed: one which includes only maintenance costs and one which includes both maintenance and renewal costs. As one would expect and as illustrated below, this can lead to significant differences in the estimation of marginal cost.

**Estimation of the cost function**

The second step is to estimate the cost function. The estimation is done by regression analysis in order to detect functional relationships between costs, infrastructure characteristics and use of the infrastructure. Usually the cost function is specified in logarithmic form (and hence each of the coefficients can be interpreted as an elasticity).

4 Information on the comparisons was provided by the Finnish member of the expert group, Mr T. Suvanto, in a paper entitled “Marginal cost differences”, 3 April 2002

5 “An Economic Analysis of Track Maintenance Costs” by Per Johansson and Jan-Eric Nilsson. Published in 1988 and updated in 2001
In all of the studies the coefficient for gross tons is significantly below unity, which means that railway infrastructure maintenance is a decreasing cost activity (it exhibits economies of density). Based on the 2001 studies, the estimation results imply that if traffic levels (gross tons) increase by 10%, maintenance costs will increase by between 1% and 1.7%.

**Determining marginal costs**

The third step is to differentiate the estimated cost function, because marginal costs are the first derivative of the total cost function. The marginal costs are calculated in relation to thousand gross ton kilometres (kgtkm). By manipulation of the function a marginal cost, averaged over the whole network, can be derived as shown in table 2.

<table>
<thead>
<tr>

<td>€0.55 / kgtkm (maintenance only)</td>
</tr>
</tbody>
</table>

Table 2 shows that in those studies where the cost function includes only maintenance costs, the marginal cost per kgtkm varies from €0.13 (Sweden) to €0.55 (Austria). Only the Finnish study in 2000 included renewal costs in the cost function. In this case the average marginal cost is much higher than those derived from other studies. The Finnish study therefore shows that renewal costs have a significant effect on marginal costs. However this is the result of only one study and it is considered that more research and testing, using more and better data as it becomes available, would be desirable.

**2.2 Finland**

The Finnish charges cover operations, maintenance and renewals cost and as such lead to a higher usage charge for the use of the network. The Finnish charge is €1.23 per kgtkm. The Finnish have also undertaken some research to evaluate what the charge would be if renewals costs were excluded. The charge in this circumstance would be €0.14 per kgtkm.

**2.3 Sweden**

The Swedish charges account only for operating and maintenance costs and not the renewal costs of infrastructure, as discussed above. This is reflected in Sweden’s relatively low charge for usage which is €0.32 per kgtkm, four times smaller than the Finnish charge. This charge is based on the 1998 Swedish study of the relationship between maintenance costs and track.

---

6 Clearly, charges per kgtkm based on a constant marginal cost over the entire network is likely to lead to some types of traffic running over some parts of the network not covering the marginal costs imposed whilst other types of traffic on other parts of the network could face charges higher than the costs imposed.
use; this study was recently updated and led to the estimates for marginal wear and tear decreasing significantly to €0.13 per kgtkm (see table above).

2.4 Austria

The Austrian model is also based on the econometric modelling approach developed by Johansson and Nielsen, including only maintenance costs within the independent variable. An average value of marginal costs across the network of €0.55 per kgtkm was derived. Dividing the network into core and supplementary lines gives a marginal cost of the core network of €0.48 and a marginal cost of the supplementary network of €3.09. The study confirmed the anticipated result that marginal costs are below average costs. All the variables used in the model, except for the age of track, have parameters which indicate a significant influence on the marginal costs of maintenance.

2.5 Observations and conclusions on the econometric modelling approach

By using the model created by Johansson and Nilsson, it is clear from the results shown above that marginal wear and tear costs of railway infrastructure can be estimated. When the estimated cost function includes only maintenance costs, the estimation results (coefficients for track length, traffic volume, etc.) are very similar in different countries (Sweden, Finland and Austria). This means that a unit change in track length or traffic volume, for example, leads to a similar change in maintenance costs in all three countries. However, the estimated marginal costs per kgtkm are different in each country. The differences can partly be explained by the different circumstances encountered in each country (e.g. differences in terrain). It is also important to recognise that countries have different systems of classification of costs. For example a cost that is classified as a renewal cost in Finland might be classified in other countries as a maintenance cost and vice versa. This is a common definitional problem. There is no clear distinction between what constitutes maintenance and renewal, particularly at the margin. This problem also extends to differentiating between renewals and enhancements. If a modern equivalent asset renewal approach is followed, it is possible that renewing the infrastructure could lead to enhanced outputs (for example, renewed track may be able to accommodate heavier axle loads). Only in one of the studies (Finland) were both maintenance and renewal costs included in the cost function7. In this case the estimated marginal costs were much higher. Even though the distinction between maintenance and renewals is unclear at the margin, it is normally possible to distinguish between the two in a large proportion of jobs and it is therefore reasonable to assume that the higher marginal costs in the Finnish study are directly related to the inclusion of more cost items in the data set than the other studies listed in table 2.

The econometric modelling approach to estimating marginal costs is very detailed and can lead to a highly detailed charging structure providing appropriate price signals and incentives. The model developed by Johansson and Nilsson appears to be well specified and potentially transferable across countries, assuming adequate data is available. However, the manner in which each approach is treated is important, particularly in relation to the inclusion of renewals costs in the independent variable. It is essential that when the various models are compared, that similar variables are used (i.e. only maintenance in all models or maintenance

7 In Sweden, adequate data on renewals was not available.
and renewal in all models). The definition of maintenance and renewals also needs to be clear. Otherwise inconsistent results can arise.

One factor which the approach does not so far appear to have analysed (probably due to the lack of adequate knowledge) is the impact of different vehicle characteristics on damage to the infrastructure and hence on maintenance costs. Although factors such as weight (gross tons) and speed are taken into account, other factors such as suspension characteristics, are not. It has been suggested that some types of track friendly suspensions cause significantly less damage to the infrastructure than other types of suspensions. Engineering knowledge on the exact relationship between suspension characteristics and asset degradation is somewhat limited at present but further research will improve our understanding significantly. It is described below how Britain has introduced differential suspension factors into its charging framework in advance of this more detailed knowledge.

In practice, constant marginal costs are used across the network, differentiated in some circumstances between passenger and freight traffic. Although this weakens the behavioral impacts which the price signals are meant to promote, it is perceived to be necessary so as not to overly-complicate the charging structure.

2.6 The usage charging model used in Britain

At the last periodic review of Railtrack’s access charges, there was considerable debate about the level of usage costs and how they should be estimated. Railtrack developed a detailed bottom-up engineering model to estimate marginal usage costs. This started from detailed engineering relationships and summed individual elements of cost caused by additional trains where these could be identified. Railtrack then “calibrated” the resulting sum of individual cost elements to the total expected cost derived from its asset maintenance plans. These plans calculated the total level of costs for different types of asset using statistical methods.

The Regulator’s consultants Booz Allen & Hamilton (BAH) developed an alternative top-down model based on the engineering relationships used by Railtrack in its model. This model assesses the total costs to the infrastructure manager of operating, maintaining and renewing the network and estimates the variability of these costs by asset category. It then allocates the variable costs across all vehicles on the network by using engineering relationships describing the relative damage caused to the infrastructure for different vehicle characteristics. It is a network-wide model and therefore the costs produced by the model are not differentiated by type of track, etc.

The Railtrack bottom-up approach had more detailed engineering accuracy, but this was spurious given the need for the Railtrack model to be calibrated to the asset lives produced by its asset maintenance plans. Further, some of the maintenance predictions from the model required calibration to Railtrack’s expectation of actual levels of activity. In terms of generating actual charges, the Regulator concluded that the detail of the bottom up model was not therefore warranted.

---

8 See for example Freightliner’s response to the UK Rail Regulator’s ‘Review of freight charging policy – Provisional conclusions’ published in April 2001.

9 Completed in October 2000. A further access charges review was completed in December 2003.

10 Railtrack was the infrastructure manager in Britain from the time of rail privatisation in 1996 until it was acquired by Network Rail in October 2002, following a year in which it was in Railway Administration.
The structure of the model
The top down model starts with total anticipated maintenance and renewal expenditure, which are multiplied by percentage variabilities by infrastructure type. This gives an aggregate variable cost.

The model also uses basic operating statistics (vehicle miles by vehicle type and tare weight) to calculate an equivalent gross tonne mile (ETM). This is the gross tonne mileage by vehicle type adjusted to take account of the technical speed of the vehicle type and other factors. The parameters used to convert actual gross tonne miles by vehicle type to ETMs are derived from a regression equation of the results from the bottom up model developed by AEA Technology and used by Railtrack.

The equivalent gross tonne mile provides an estimate for the unit of damage for a particular vehicle type. The cost per ETM is then calculated by dividing the aggregate variable cost by the ETM measure for an individual vehicle type. This value is multiplied by an appropriate ratio to convert it to the desired units (for example, pence per vehicle mile).

Inputs to the top down model
Total maintenance and renewal expenditure
The starting point for the top down model is the total maintenance and renewal expenditure, which derives from the total revenue requirement of the infrastructure manager. The expenditure figures used in the top-down model take account of efficiency gains which it was assumed Railtrack would achieve by the middle of the control period (September 2003).

Variability of costs by asset type
The percentage variability of the maintenance and renewal costs for different asset types is shown in table 3.

Source: Booz Allen & Hamilton: “Usage costs: issues raised in the Regulator’s consultation” October 2000
These variabilities were determined by BAH mainly through consideration of the AEA Technology work on usage costs and experience of other rail networks. The variability of track maintenance costs has been set at a level consistent with US experience at tonnages equivalent to those experienced by Britain’s railway network.

**Vehicle characteristics**

The vehicle characteristics which are used as the determinants of infrastructure damage within the model are speed, axle-load and unsprung mass for both passenger and freight vehicles. In addition, suspension type and coal dust spillage are further determinants of cost for freight vehicles. Seven suspension type categories have been used, each of which has a different damage factor. These are not based on known engineering relationships but were considered important to introduce at that stage to incentivise freight operators to use more track-friendly equipment.

**Parameters**

The parameters (taken from the AEA Technology work) translate the different vehicle characteristics into damage factors. There are different parameters and hence different damage factors for track and structures.

**The form of the charge**

Railtrack proposed that usage charges be based on consist mile by different consist compositions (where a consist is the particular composition of a train) to increase the cost reflectivity of the charges. It would also substantially increase the complexity of usage charges. The Regulator’s subjective evaluation was that Railtrack’s proposed increase in cost reflectivity would be outweighed by the complexity that such disaggregation would introduce. Railtrack also proposed geographical and asset type disaggregation. However, the Regulator believed that this would distort Railtrack’s incentives in relation to track quality or design and could result in confusing and complex price signals to national train operators (freight operators in particular). As a result, the Regulator therefore believed that usage charges based on geography or asset type would not be appropriate. This would, however, be kept under review.

The usage charges derived from the top-down model are therefore network-wide averages. They are disaggregated by type of vehicle.

**Results of the model**

The marginal cost per locomotive km (averaged across all locomotives) is €0.464; the marginal cost per coach km is an average of €0.096; the marginal cost per diesel motor unit km is an average of €0.099; and the marginal cost per electric motor unit km is an average of €0.100. The average of these costs across all passenger traffic is €0.190. For freight wagons, the variable cost, averaged across all wagons, is €3.1 per kgtkm.

These charges incorporate expected efficiency savings. The variable charges for passenger services were set assuming savings equal to 3.1% per annum over the control period (5 years).

---

11 These figures were calculated by taking the pence per vehicle mile quoted in the “Periodic review: final conclusions, Volume II” (in 1998/99 prices), converted into pence per vehicle kilometre and then converted into euros per vehicle kilometre at an exchange rate of €1=£0.61.
The Regulator believed that there was a compelling case for taking a longer-term view of efficiency in relation to most freight traffic. This is because long-term efficient charges would enable operators to plan their businesses with a reasonable degree of assurance and should help to achieve the UK government’s growth targets for rail freight traffic. As a result, the Regulator concluded, apart from the exceptions discussed in the paragraph below, that for all freight services, freight access charges should assume ten years of efficiency improvement at 3% per annum.

The longer-term view of efficiency does not apply to rail-freight traffic carrying coal for the electricity supply industry and iron ore. This is because these freight flows are not generally as price-sensitive as other freight flows since in both markets rail already enjoys a high market share with a clear competitive advantage over road. This means that such traffic would not be in danger of being priced off the network as a result of non-application of the long-run efficiency assumptions but also that there would exist limited opportunities for modal shift between road and rail.

3. Comparative analysis between Britain, Sweden, Finland and Austria

The Swedish (and hence Finnish and Austrian) approach and the British approach to the estimation of variable track access charges are similar in that they are both top-down estimates. In the Swedish case, the estimate is based on original econometric analysis whereas the British analysis is based on a literature search of econometric and engineering studies. Having established costs per gkm, the British approach then goes further in distributing this cost across vehicle types on the basis of engineering studies.

There are substantial differences between the marginal cost estimates in the Swedish and British approaches. Conclusions on the differences between marginal costs should be drawn with an understanding of the inherent deficiencies of the input data used in the various models, a point also made by Johansson and Nilsson. Research into this area in the context of separated infrastructure managers and train operators is relatively recent. Whilst the results of the various studies raise a number of interesting issues, these should form the basis for ongoing research. The validity of the preliminary results, and their use in a policy context, need to be confirmed by logic, engineering judgement and experience. Nevertheless, some important factors which probably contribute to differences in marginal costs are suggested below.

3.1 Scope

The Swedish study assesses maintenance costs alone, whereas the British study looks at both maintenance and renewal (re-investment) costs. The Finnish application of the Swedish model uses both maintenance and renewal and demonstrates that renewal costs are some 8 times higher than maintenance costs per gkm.

3.2 Definitions

Britain’s costs relate to infrastructure maintenance and renewal, not simply track. The Austrian application addresses the maintenance of electrification assets separately, but the
status of other infrastructure maintenance activities (signalling, telecommunications, etc) is unclear.

As stated above, there is no universally agreed distinction between what constitutes ‘maintenance’ and what constitutes ‘renewal’. Cross-country comparisons are therefore difficult at an aggregate level and require much more detailed work on cost classification.

The difference between British and Finnish track renewals costs is some 35% whereas the difference between track maintenance costs is 830%. However, it is necessary to examine the maintenance strategies of each railway before drawing firm conclusions on these statistics – a policy of life extension of assets, for example, as pursued by the British infrastructure manager in the past, would tend to increase maintenance costs and reduce renewals costs, both in aggregate and per gkm. Overall, the combined maintenance and renewals cost difference is some 133% between Britain and Finland.

The British estimate of variability of track maintenance costs is rather higher than the Swedish (at an average of 30% rather than a range of 12-28%). This follows from the fact that the British estimate draws in particular from US experience (notably, the American Railways Engineering Association), which estimates variability across a range of traffic densities over time. This estimate will therefore include the effects of long term traffic growth on track quality, i.e. it will reflect the need to improve track quality and standards as traffic volumes grow – an important consideration in Britain as traffic volumes have been increasing rapidly. The Swedish estimate is essentially cross-sectional, on a traffic base which is not experiencing such high growth, and will therefore tend to exclude such factors.

### 3.3 Unit costs

Even if the activities undertaken in maintenance actions are identical between comparators, there may still be substantial differences in the cost of resources used to undertake those actions – both in terms of costs per man-hour, costs of materials and production technologies. These can lead to significant differences even within the same network – on the British network, for example, differences of 130% were discovered during the periodic review of 2000 between the costs of re-railing in the south of the country compared to Scotland.

Across international boundaries, there will also be other differences relating to exchange rates and accounting policies, such as differences in the treatment of pensions costs, etc.

### 3.4 Composition of costs

**Risk**

British railway maintenance and renewal under Railtrack were wholly outsourced. The contracts were essentially output-based, with the contractor undertaking to provide whatever inputs were necessary to secure the contracted levels of track quality, etc. Maintenance costs in Britain therefore included the costs of carrying this output risk. Although maintenance and renewal works are outsourced in Sweden, Finland and Austria, these tend to be focused more on inputs. In consequence, output risks are being taken by the infrastructure managers themselves and not necessarily monetised (or perhaps even recognised).

Of course, one of the benefits of output-based contracting is presumed to be a reduction in costs by allocating risk to those best able to manage it and therefore Britain’s maintenance
costs might have been expected to be lower than those elsewhere – but only if contracting in Britain is efficient, which it probably isn’t at the present time. Therefore, the reported costs of maintenance may be higher in Britain than elsewhere.

**Internal charges**
The privatisation process in Britain externalised a number of “contractual” relationships which were previously internal within the railway companies. One example is the costs of engineering trains, both those carrying materials from factories/quarries to storage, those from storage to work sites and those carrying spoil (waste) from works sites. In Britain, the costs of these trains are equivalent to about 30% of total track renewals costs but were previously not recognised or properly captured. Another example is the cost of taking engineering possessions, i.e. compensating train operators for taking sections of line out of service for maintenance/renewal activities. Historically, however, compensation has only been paid for disruptive possessions which have not been pre-booked. The addition to cost from this factor though is likely to be modest.

**3.5 Derivation of Maintenance Budgets**

Maintenance budgets for the Swedish, Finnish and Austrian rail infrastructure managers are drawn from Government. In such circumstances, there may be no close linkage between maintenance need and maintenance budgets. It is a common phenomenon in railway history, for example, for track maintenance to be reduced at a time of budgetary constraints. In Britain, there is a closer linkage as there is a requirement to maintain track condition and quality.

However, it is not necessarily the case that, in practice, there are stronger incentives on the British infrastructure manager to be more efficient than its counterparts. As noted by Johansson and Nilsson, there is no evidence that professional railway engineers are any less incentivised in Sweden to be cost minimising.

**3.6 Technical issues**

There are a number of technical, engineering issues which need to be taken into account when comparing maintenance costs between railways. For example, existing track condition and the integrity of the original construction of the track have both been found to be important determinants of maintenance needs and therefore costs. Differences in traffic densities, track standards and safety requirements would also generate differences in expenditure requirements.

**4. Other elements of marginal social cost**

**4.1 Charging for environmental externalities and accident costs**

The expert group believed that the introduction of charges (for all modes) to account for environmental externalities is desirable and would provide appropriate incentives both within the rail industry and across different modes. However, it was recognised that the optimal
approach would be to introduce environmental charges in rail only once similar charges are introduced for other modes of transport. The current ‘best practice’ for estimating and implementing environmental charges are the approaches adopted in Sweden and Finland. Nevertheless, only a few components of environmental costs are incorporated. Also described in this section is Sweden’s and Finland’s approach to implementing charges to reflect accident costs.

**Sweden**

**Emission costs and charges**

Sweden has an environmental charge based on nitrogen oxide emissions from diesel traction, differentiated by locomotive. The current level of charges represents a small proportion of the total external costs. The environmental impact of rail transport includes noise and vibration, land take, air pollution and climate impacts.

**Accident costs and charges**

The original Swedish accident charge, introduced in 1988, was based on a total cost allocation principle. The total external accident costs of railway accidents were allocated to the total number of train kilometres. No pure marginal cost analysis has been carried out. In 1998, when the latest charging scheme was introduced, the accident charge was differentiated between passenger and freight. The charge included only non-level crossing accidents.

Since then there has been more work on level crossing accidents in the UNITE project. The project considered road/rail level crossing accidents and costs related to personal injuries, with the aim of understanding the relationship between rail traffic volume and accident costs.

**Finland**

**Emission costs and charges**

Finland has an emission charge, derived from a study undertaken in 1998. The objective of the study was to measure and value the environmental costs caused by rail traffic emissions. The review covered the Finnish railway operator’s diesel and electric traction traffic in 1996. The environmental impact of diesel trains was assessed separately for urban centres (with concentrated centres of population) and rural areas. The environmental cost of electric trains was estimated based on the source of electricity supply (renewable sources or otherwise). The valuation method used was the Impact Pathway Method, which consists of four steps: emission inventory; dispersion calculations; quantification of impacts; and their monetary valuation. The impacts studied included health effects (mortality and morbidity), materials damage, ecological effects (forest and crop damage) and climate change.

The results of this study revealed higher costs than those derived from comparable international studies, but were of the same order of magnitude, both for electric and diesel traction.

The marginal emission charges in Finland are €0.098 per kgtkm for passenger traffic, €0.39 per kgtkm for diesel-powered freight trains, and €0.197 per kgtkm for electric-powered freight trains. The unit values of these charges are updated every three years.

---

12See Lindberg
Accident costs and charges
The accident charging framework in Finland is based on a study by Tervonen and Juha. This report suggests a framework for categorizing and assessing the internal and external costs of railway accidents. The focus is on personal injuries and allocation of cost responsibility. The cost is categorized by type of accident and according to the severity of injury. The accident categories are: collision or derailing; level crossing accident (with and without warning device); falling from a platform or moving train, and accidents from trespassing.

The key criterion in distinguishing between internal and external accident costs is the exposure of risk in different accident categories. In the case of collision, derailing or level crossing accidents with warning devices, the passengers, train personnel and motorists are aware of their personal risks. Therefore, risk values are internalised for their part in all accidents. The remaining external costs are the costs to authorities and lost national product. However, in the case of accidents at level crossings without warning devices, or falling onto tracks from platforms or from moving trains, the risk costs are considered externalities, since careful behaviour may have not prevented the accident.

The external costs of accidents at level crossings without warning devices are allocated between rail and road transport modes. The costs of accidents on platforms and accidents to passengers falling from moving trains are allocated to the railways. The costs of accidents to pedestrians who trespass on rail lines are not considered the responsibility of the railways.

Cost assignment is based on a recent updating of the socio-economic unit costs of personal injuries. Marginal external costs of accidents are estimated by applying these unit costs to currently available accident risk models, at least for level crossing accidents.

The marginal accident charges in Finland are €0.92/kgtkm for passenger traffic, €0.064/kgtkm for electric powered freight traffic and €0.1764/gtkm for diesel powered freight traffic.

Other findings
It has been suggested that, from an incentive viewpoint, differentiation of charges to reflect environmental externalities within the rail mode is desirable even in the absence of environmental charges faced by other modes. Charges for relatively environmentally friendly locomotives and rolling stock could be reduced from the base level of charges, whilst charges for more environmentally damaging locomotives and rolling stock could be increased above the base level, ensuring that the expected revenue to the infrastructure manager is held constant. However, if such differentiation of charges had the desirable behavioural effect, this would lead to the infrastructure manager under-recovering its costs.

Summary of environmental charges
Much research has been conducted in recent years in establishing methods for assessing the environmental impacts of transport and in quantifying these impacts. The application of emissions and accident charges in Finland and Sweden illustrate that implementation at a practical level is possible. However, both the Finnish and Swedish members of the expert group felt that the area of marginal environmental costs (including costs not yet captured in their charging frameworks) would benefit from further research. Consistency of approach across Member States would also be desirable.
4.2 Capacity/Congestion charges
Capacity charges (or congestion charges) are levied in Britain and are set to recover the infrastructure manager’s increased congestion costs which result from running an additional train on the network. These are the increase in the infrastructure manager’s expected costs through the contractual performance regimes from adding an additional train into the timetable, because reducing the gap between services makes it more difficult and costly for the infrastructure manager to manage the knock on effects of an initial delay (known as reactionary delay). The capacity charges were determined using modelled relationships between delay and capacity utilisation across the network. This is not a demand management tool in the way described in the scarcity pricing section set out below (section 3).

4.3 Scarcity pricing
The expert group determined that there is currently no ‘best practice’ in scarcity pricing. It is important to stress that the use of pure scarcity pricing to equate supply and demand without complementary administrative rules, regulations and procedures is unlikely to be implemented in many countries. Examples might include:

- member states wanting to ensure that some capacity is reserved for rail freight operations which might otherwise be priced off the network;
- member states wishing to regulate certain fares or freight tariffs in the public interest. Demand for train paths is a derived demand and therefore fare regulation in the downstream market could impact upon the effectiveness of scarcity pricing to allocate capacity efficiently in the upstream market.

The expert group pointed out that there is a trade-off between managing demand through scarcity pricing and increasing supply (providing additional capacity) through enhancements to the network. This trade-off is clearly illustrated in network industries where investment is lumpy and capital costs are large. For example, if demand only exceeds capacity by a small amount at the prevailing marginal cost, it may be appropriate to introduce scarcity pricing in the short-term rather than increase supply through costly investment, such that demand and supply are brought back into line. As demand continues to grow relative to the fixed supply, scarcity prices will have to increase to maintain equilibrium. A point will be reached when the socially optimal level of infrastructure will increase and capacity enhancement will be justified in economic terms.

The expert group concluded that scarcity charging is one of the most complex issues to deal with in the rail industry. It recommended that there needs to be more research into scarcity pricing and auctioning of capacity in the rail industry before it can be effectively implemented. In particular, there needs to be more emphasis on overcoming practical difficulties in the implementation of scarcity charging.

4.4 Traction electricity charges
In Britain, where operators use traction electricity, they currently purchase this from the infrastructure manager, who in turn purchases its aggregate requirements from competing electricity suppliers. The charges for traction electricity, by geographical area, are designed to be broadly cost reflective and to ensure that the infrastructure manager is incentivised to
procure electricity efficiently for the railway industry. There is a downward adjustment to traction electricity charges where operators use regenerative braking.

5. Conclusions

This paper has presented a summary of the findings of the expert group on best practice in marginal cost pricing. It shows that although knowledge of cost drivers in railway infrastructure needs to be developed further, a number of countries have adopted marginal cost-based pricing strategies which could be adopted by other Member States when implementing the charging principles laid out in Directive 2001/14/EC. It was agreed by the expert group that the two approaches to determining marginal wear and tear costs described in Section 2, namely the econometric modelling approach used in Sweden, Finland and Austria and the approach used in Britain, could be considered as current best practice. There remains an inconsistency of approach to determining marginal wear and tear costs even between countries which use the same modelling framework. This inconsistency arises, in particular, with the inclusion or otherwise of renewals costs. Of those countries which have adopted the econometric modelling approach, only Finland has included both maintenance and renewals costs within the independent variable. This appears to have a significant effect on the level of marginal costs.

Section 2 set out a number of differences between the various models used and showed that there is a large variance in the amount that is charged in each country (to cover wear and tear costs) for access to their respective networks. It was suggested that this might be due to a number of factors, including definitional differences (i.e. between maintenance and renewals), different unit costs, different composition of costs, the difference between maintenance needs and maintenance budgets, and technical issues. Importantly, it was recognised that conclusions on the differences between marginal costs should be drawn with an understanding of the inherent deficiencies of the input data used in the various models. Research into this area in the context of vertically separated industries is relatively recent. Whilst the results of the various studies raise a number of interesting issues, these should form the basis for on-going research.

Section 3 set out a number of other areas of marginal social cost, besides wear and tear costs, implemented by various Member States. These remain relatively new areas of charging but the application of emission and accident charges in Finland and Sweden and the implementation of congestion charging in Britain illustrate that implementation at a practical level is possible.

Scarcity pricing, in particular, is an area where further research is needed before robust economic pricing frameworks can be developed for demand management and capacity allocation. It was suggested that pure scarcity pricing to equate supply and demand without complementary administrative rules, regulations and procedures is unlikely to be implemented in many countries.
